Abstract

The study focuses on the population of bowhead whales in West Greenland, an area with history of exploitative whaling practise. The aim of the study is to estimate and analyse the bowhead whale and their group abundance using conventional distance sampling. A model using a half-normal detection function with no adjustments was selected. It estimated the probability of detection of individual bowhead whales to be

Introduction

Accurate estimation of animal populations is essential for wildlife management and conservation, as it helps to determine population numbers, monitor trends, and evaluate the effectiveness of conservation efforts (Elton, 1950; Bourlière, 1954). Animal populations are affected by various factors such as demographic, ecological, and human-related factors. Bowhead whales were commercially hunted in the early 16th century, leading to a drastic reduction in their population by the end of the 19th century. This led to research on their population and abundance in West Greenland, an area where their behaviour and activities are reliable indicators of population size and structure. One such area is Disko Bay, which has seasonal occurrences of bowhead whales. The International League of Nations agreed on worldwide protection of the species in 1931 to ensure their survival, and monitoring the abundance of their populations has remained crucial for their conservation today (Heide-Jørgensen, M.P. et al., 2007; Barkham, 1979; Woodby & Botkin, 1993; Rekdal et al., 2015).

This study assesses the detectability and abundance of bowhead whales in Disko Bay using distance data from the survey conducted by Rekdal et al. (2015). Based on the aerial survey, the number of bowhead whales in Disko Bay in 2006 was estimated to be 1,229 (CV = 0.47, 95% CI: 495-2,939) (Heide-Jørgensen et al. 2007). In this report, a sample representative portion of the area, i.e. plot distance sampling, is used to estimate the abundance. This methodology is widely used in ecological surveys to account for imperfect detections.

Methods

To collect data on bowhead whales, visual aerial line-transect surveys were conducted in coast land offshore areas in West Greenland between 65°400N and 75°300N, largely covering the area of the local spring aggregation in Disko Bay (Rekdal et al., 2015). The study region of 242,650km² was divided into 16 strata based on prior knowledge of anticipated densities of bowhead whales. Between 24th March and 14th April 2012 7836.5km of total east-west oriented transect lines were observed, with the targeted altitude and speed being 213m and 167 km/h respectively, the maximum perpendicular distance was set to 2,500m. Surveying was only carried out if

Beaufort Sea States Code was 2 or less, i.e. only when the sea was calm. Inclinometers were used to measure the angle of declination for each observed group of bowhead whales (Suunto). Due to an obscured view close to the transect line, detections were left-truncated at 100m (Rekdal et al., 2015).

The bowhead whales further away are less likely to be detected, thus distance is employed as a detection bias. The detection function in distance sampling describes how detectability varies with distance, it includes the proportion and probability of animals being seen at a given distance.

8 models were fit to the distance data using all combinations of hazard-rate $g(x) = \exp(-(x/\sigma)^{-b})$, and half-normal $g(x) = \exp(-x^2/2\sigma^2)$ detection functions with cosine, hermite polynomial and simple polynomial adjustments. These functions use σ as a scale parameter (“standard deviation”) and b is used in hazard-rate functions to control the width of the shoulder.

Model selection using Akaike information criterion (AIC) found that the best model was a half-normal with no adjustments. AICc was also applied due to the ratio of model parameters to observation being less than 1:40 and found the same result (Takezawa, 2014). This model had a good fit; Cramer-von Mises test ($T = 0.073$, $p = 0.732$), bootstrap Kolmogorov-Smirnov test for goodness-of-fit ($D = 0.073$, $p = 1$). Additionally, a QQ plot comparing empirical and fitted CDF had points lying approximately on the 1:1 line.

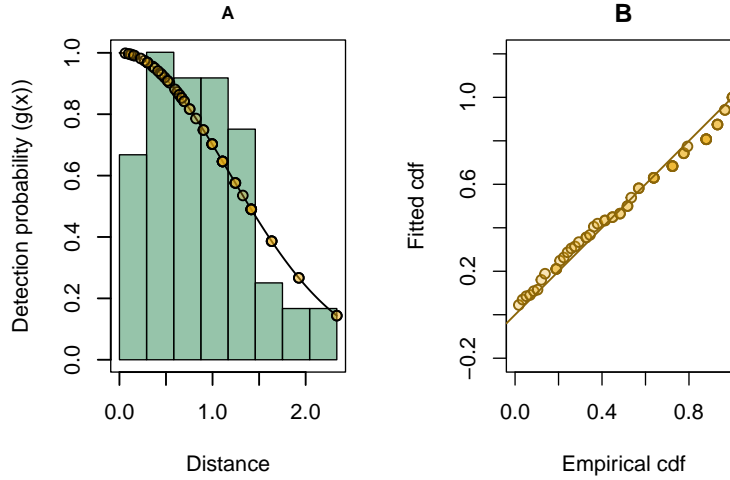

Figure 2: Half-Normal No Adjustment Model Fit. A is the model fit over the distribution of distances. B is the QQ-plot of the expected vs observed CDF

Figure 2: Half-Normal No Adjustment Model Fit. A is the model fit over the distribution of distances. B is the QQ-plot of the expected vs observed CDF

Results

Individuals

The model estimated the average detectability of **individual** bowhead whales to be 0.47. For individual Bowhead whales, the estimated abundance was highest in strata 2 (138.83, 95% CI = 291.53; 66.11) and lowest in strata 15 (5.12, 95% CI = 39.44; 0.67) (see figure 2). The total estimated individual abundance was 228.82 (95% CI = 122.00; 429.14) (see figure 2). Additionally strata 2 has the biggest difference in observed abundance compared to estimated abundance with 65 whales seen and 138.83 estimated (see figure 2).

The model estimated the average detectability of **clusters** of Bowhead whales to be 0.61. Bowhead whale clusters were estimated to have the highest abundance also in strata 2 (106.79, 95% CI = 49.53; 230.28) (see figure 3) which also has the largest difference between observed and estimated abundance (50 - 106.79). The total estimated cluster abundance was 183.93 (95% CI = 94.62; 357.54) (see figure 3)

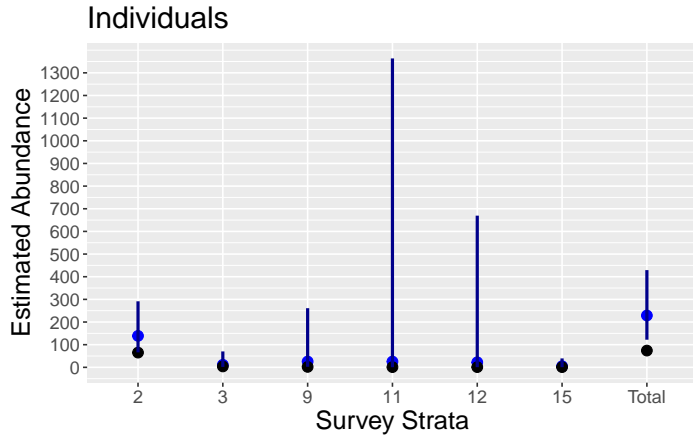

Figure 3: The estimated abundance of Bowhead whale individuals in each strata (blue dots) and the confidence intervals for the

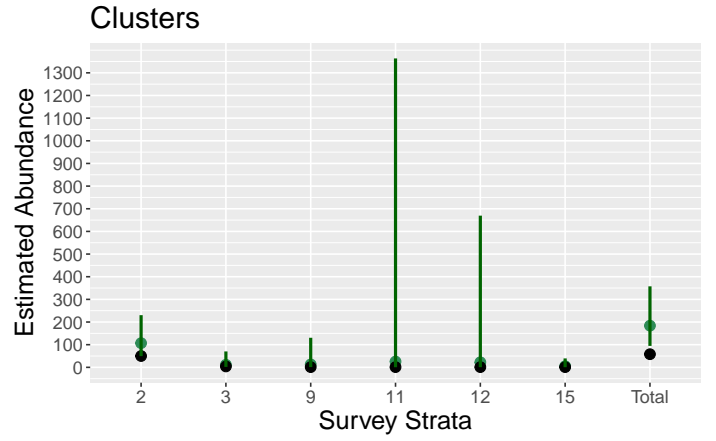

Figure 3: The estimated abundance of Bowhead whale clusters in each strata (green dots) and the confidence intervals for the ab

Table 1: Abundance Estimates for Individuals, Abundance Estimates for Clusters

Individual Abundance Estimates	Lower CI	Upper CI	“ ”	Cluster Abundance Estimates	Lower CI	Upper CI
138.83	66.11	291.53		138.83	66.11	291.53
11.31	1.82	70.25		11.31	1.82	70.25
25.70	2.53	261.12		25.70	2.53	261.12
25.53	0.48	1363.51		25.53	0.48	1363.51
22.33	0.74	669.55		22.33	0.74	669.55
5.12	0.67	39.44		5.12	0.67	39.44
228.82	122.00	429.14		228.82	122.00	429.14

Discussion

The estimated abundances suggest there are most individual and clusters of Bowhead whales in stratum 2 however there is a large amount of error visible in the large confidence intervals. This is most likely due to the small number of detections of whales in each stratum for example in strata 9,11,12 and 15 only one sighting was recorded. Therefore to get more accurate measurements of Bowhead whale abundance, a second survey should be conducted over the same region. The perpendicular distance distribution of detections revealed a slight reduction in detection frequency close to the transect line, implying a somewhat obscured view, which would result in underprediction. Detections were, therefore, left-truncated at 100 m, satisfying the assumption of perfect detection at this distance. As inclinometers were used to measure the angle of declination, perpendicular distances from line to animal are uniform random variables. Distances have been measured using targeted plane altitude and speed, indicating that the survey was completed with great care and that it was accurately measured to the initial plane location. As of the data surveying description, it is concluded that the assumptions have been satisfied.

For future studies, surveys could be collected over years and compared as time series data to inspect if there are changes in the abundance.
